**ABSTRACT**

**Motivation:** The rapid development of high-throughput sequencing technologies has enabled epigeneticists to quantify DNA methylation on a massive scale. Progressive increase in sequencing capacity presents challenges in terms of processing analysis and the interpretation of the large amount of data; investigating differential methylation between genome-scale data from multiple samples highlights this challenge.

**Results:** We have developed a differential methylation analysis package (DMAP) to generate coverage-filtered reference methylomes and to identify differentially methylated regions across multiple samples from reduced representation bisulphite sequencing and whole genome bisulphite sequencing experiments. We introduce a novel fragment-based approach for investigating DNA methylation patterns for reduced representation bisulphite sequencing data. Further, DMAP provides the identity of gene and CpG features and distances to the differentially methylated regions in a format that is easily analyzed with limited bioinformatics knowledge.

**Availability and implementation:** The software has been implemented in C and has been written to ensure portability between different platforms. The source code and documentation is freely available (DMAP as compressed TAR archive folder) from http://biochem.otago.ac.nz/research/databases-software/. Two test datasets are also available for download from the Web site. Test dataset 1 contains reads from chromosome 1 of a patient and a control, which is used for comparative analysis in the current article. Test dataset 2 contains reads from a part of chromosome 21 of three disease and three control samples for testing the operation of DMAP, especially for the analysis of variance. Example commands for the analyses are included.

1 **INTRODUCTION**

DNA methylation is arguably the most stable epigenetic mark that plays a key role in regulating development and disease (Baylin and Bestor, 2002; Law and Jacobsen, 2010). One of the most fundamental challenges for epigeneticists is to identify DNA methylation differences between genomes. For instance, differential methylation between diseased and normal samples, interindividual variation within a population, differences between tissues or species and so on are of biological and clinical relevance.

The rapid improvement in next-generation sequencing technologies now provides opportunities to interrogate DNA methylation at single base resolution with high coverage across multiple samples. Bisulphite treatment converts unmethylated cytosines to uracils (and ultimately to thymine after amplification), although leaving methylated cytosines unchanged. Therefore, bisulphite treatment combined with next-generation sequencing (BS-Seq) has become a preferred method to generate base-resolution DNA methylation maps. Because whole-genome bisulphite sequencing (WGBS) is still expensive and generates challenging amounts of raw data, reduced representation bisulphite sequencing (RRBS) provides a cost-effective alternative for whole-genome methylation sequencing. RRBS has been widely used by several groups worldwide to interrogate functionally important genomic regions at high-resolution coverage and sensitivity (Baranzini et al., 2010; Bock et al., 2011; Chatterjee et al., 2012; Gertz et al., 2011; Gu et al., 2010; Smallwood et al., 2011; Steine et al., 2011; Xi et al., 2012).

During the past few years, several alignment tools have been developed to cope with asymptotic mapping issues of bisulphite converted sequenced reads and to map millions of reads with reasonable speed to the reference genome. Some of these aligners are RMAP (Smith et al., 2009), BS Seeker (Chen et al., 2010), Bismark (Krueger and Andrews, 2011), RRBSMAP (Xi et al., 2012), BatMeth (Lim et al., 2012) and PASS-bis (Campagnola et al., 2013). Recent comparative analyses have improved our understanding of the efficiency, accuracy and algorithm of these aligners (Chatterjee et al., 2012; Kunde-Ramamoorthy et al., 2014). Additionally, tools have been developed for generating methylation calls and visualization. Integrated Genome Viewer (Thorvaldsdottir et al., 2013) and MethVisual (Sun et al., 2013) allow visualization of sequenced reads and regional analysis. BiQ Analyzer HT allows site-specific DNA methylation analysis (Schmieder and Edwards, 2011), and SAAP-RRBS can perform alignment, methylation calls, annotation of CpG sites and visualization (Ziller et al., 2013).

methylKit (Akalin et al., 2012a), an R package, enables detection of differentially methylated CpG sites (DMCs). methylKit
DMAP: differential methylation analysis package

2 METHODS AND ALGORITHMS

2.1 DMAP package and input data

DMAP contains two main programs. (i) **diffmeth**: The input files to **diffmeth** are either SAM files from Bismark alignment (Krueger and Andrews, 2011) or the older native format produced by the Bismark methylation_extractor program, comprising a single line for each mapped CpG giving the chromosome, the CpG position and the methylation status (+/-). Alternatively, if other aligners (such as BSMAP and RMAPPBS) are used, then the files (BED file or text files) can be processed by the rmapbscpg2 ancillary program before analysis with **diffmeth**. By default, **diffmeth** does not impose any P-value cutoff for identifying DMR; it returns a P-value for each investigated region/fragment to allow user-specified threshold P-values and independent application of multiple test corrections.

(ii) The final output file from **diffmeth** program can then be used in the second main program of DMAP, **identigeneloc**, to identify proximal genes and features (transcription start sites, exons/introns, etc.), relationship to CpG features (CpG island core/shore/shelf) and distances from each feature (Fig. 1). This operation is performed by a command-line program, which reads genomic feature table information and relates candidate regions from the previous step to annotated features. The application uses code originally developed in another context (Jacobs et al., 2009) and is capable of parsing feature table information from GenBank, EMBL, GTF, GFF3 and SeqMonk feature files, although the latter has been extensively tested. If SeqMonk feature table information is used (-Q switch), then it is possible to specify biotype for a gene (e.g. protein coding, pseudo-gene, miRNA). Supplementary Information 2 and the program document contain a user guide to set up the software and a step-by-step instruction manual for operation of the analysis pipeline.

2.2 Units of DNA methylation analysis

2.2.1 DMC approach

Differential methylation patterns can be investigated in several ways. One of the approaches is to analyze each CpG site (with adequate coverage) in each sample and then to identify DMCs. DMAP permits the user to interrogate the methylated (represented as + sign) and unmethylated (represented as – sign) counts for single CpG sites (e.g. Table 4) in the datasets, but does not have options for detecting DMCs.

2.2.2 DMR approach

Use of a fixed or sliding window (typically 1000 bp length) as a unit of methylation analysis is another common approach for detecting DMRs (Bock et al., 2012; Li et al., 2010). DMAP includes options for investigating differential methylation on a user-specified tiled window of any length. Although the tiled DMR approach is well-suited for WGBS, for RRBS protocols, a fixed or sliding window of any length might dilute this variation (Ehrlich and Lacey, 2013). A DMC approach is perhaps more useful when a small number of CpG sites are analyzed.

2.3 Implementing MspI fragments as a unit of analysis for RRBS (DMF approach)

For RRBS, we introduced a new MspI fragment-based approach for investigating DNA methylation. This approach is conceptually similar to the DMR approach, but instead of fixed-length windows, MspI-digested fragments of 40–220 bp lengths were used as the unit of analysis. After Bismark alignment, the methylation_extractor program returns information for each mapped CpG site, its genomic position and methylation status. **diffmeth**
scans the genomic sequence of each chromosome for MspI cleavage sites and CpGs, building a list of those conforming to the required size range of 40–220 bp. For each sample, the methylated and unmethylated CpGs are checked to find the fragment on the list (if any) to which the CpG positions match and the methylated and unmethylated counts are incremented. This information was used to calculate coverage (\(+/\) and \(/-\) counts, where + is a methylated CpG and – is an unmethylated CpG) and quantify the methylation of each fragment. Then based on a coverage cutoff (different cutoff criteria for filtering fragments can be applied; see details in documentation), fragments with low sequencing coverage were discarded, and a list of fragments and their methylation status were produced for each sample. Appropriate statistical tests and a P-value can then be applied to identify DMFs. The sequenced reads in RRBS come from MspI-digested fragments, and as one CpG site is included in the recognition site (C'CGG) of the enzyme, each fragment will contain at least one valid analyzable CpG, irrespective of the CpG density of the region. DMAP provides flexibility in the choice of coverage criteria to include fragments from both CpG-poor and CpG-rich regions (see documentation for setting coverage threshold).

While implementing the fragment-based approach, adjacent MspI fragments posed a computational challenge. If two fragments are adjacent, then the methylation counts of the mapped reads, which start from the junctional MspI site, could be counted in either of the fragments, as in the genome they share the same location. However, for an accurate coverage calculation for the fragments, the methylation counts from the CpG at the junction of two adjacent fragments are attributed to the fragment from which they were derived (see Supplementary Information 1, section 7, for detailed demonstration of this behavior).

To ensure correct attribution of junctional CpG methylation, we added a feature to DMAP that uses the data from the SAM files (with the –N switch) to retain the identity of the strand onto which a sequenced read is mapped. Then for the reverse strand-mapped reads, the program identifies the fragment to which these reads were mapped and accumulates the CpG information for that fragment, including the first CpG site of the read but not for the succeeding adjacent fragment. In the reference genome, the last CpG site of an MspI fragment and the first CpG site of the adjacent fragment are the same, but after this correction, CpG information from the overlapping reads was counted under the fragment from which the reads were derived.

Non-specific activity of the MspI enzyme and partially degraded DNA could result in sequenced reads without a MspI start site. For RRBS, 29% non-MspI sequenced reads has been reported (Akalin et al., 2012b). However, we observed

Fig. 1. Flow diagram of options and analysis units in DMAP
a lower prevalence of non-MspI reads in our test RRBS libraries (median percentage of non-MspI reads = 8.1; n = 11). Presence of non-MspI reads might affect unique alignment but does not influence DMAP. DMAP calculates methylated and unmethylated counts for each CpG site in a fragment; therefore, a fragment will qualify for subsequent analysis if sufficient reads had uniquely mapped to it, irrespective of the base composition of sequenced reads (i.e. MspI or non-MspI start of a read).

In a MspI-fragment, the CpG sites are likely to show more similarities in terms of read coverage and DNA methylation levels compared with the CpG sites in a large DMR. Further, as a fragment is a contig of sites, it will decrease the sampling and technical variation to a greater extent. Therefore, we believe the fragment-based approach is the intermediate approach to DMR/DMC approaches and perhaps better suited for RRBS data.

### 2.4 Statistical tests to identify DMF and DMR

The Fisher’s exact test over a sliding window with a specified fold difference is a widely used approach for assessing differential methylation between two samples or groups of samples (Bock et al., 2010; Glastad et al., 2013; Gu et al., 2010; Ivanov et al., 2013; Li et al., 2010). For RRBS data analysis, for a given MspI fragment, Fisher’s exact tests can be performed between multiple samples by giving a continuous list of SAM files in the command in diffmeth tool of DMAP package. In this case, the probability of multiple pairwise tests will be given and the lowest probability taken to indicate the extent of differential methylation, although this may obscure a number of insignificant differences between other samples.

To investigate the extent of interindividual variability in DNA methylation across multiple samples, we have used a Chi-squared test. To perform this test, a list of SAM files should be provided as an input to diffmeth. Various thresholds can be applied to restrict the tests to fragments and samples that meet criteria for CpG number, density of CpG mapping and fold difference. For WGBS data, instead of fragments, tiled windows of defined length can be investigated in a similar way. Output from this part of DMAP consists of a line for each qualifying fragment or region giving the chromosome number, region start and end positions, length, CpG count, coverage, the probability and the type of statistic applied (Fig. 1 and Table 3).

Classifying subjects into treatment or disease versus control groups is a usual task in DNA methylation analysis. To compare methylation between two different groups, one strategy is to concatenate the CpG position files or SAM files for each group and perform a pairwise comparison. However, this might lead to significant data loss while comparing multiple samples. A better strategy is implemented in DMAP using ANOVA and the F ratio test to determine the significance of methylation differences between the groups in relation to the residual variation within each group. ANOVA runs allow SAM files to be assigned to either of two groups, generating an F (1, n) value where n depends on the number of qualifying individuals for each region or fragment. The statistical significance of the F statistic is estimated using a continued fraction iterative method (Press et al., 1993).

### 3 RESULTS AND OUTPUTS

#### 3.1 Reference methylome

DMAP can produce reference methylomes for individual samples after filtering regions with a specified coverage criterion [for example, reference methylomes can be based on MspI fragments (for RRBS) or user-specified tiled windows]. Table 1 shows the diffmeth output from a fragment-based methylome for a human RRBS library generated from peripheral blood. A similar output based on 1000 bp tiled windows is shown in Table 2 for a different region of the same dataset. These outputs are produced as text files, which can be easily subjected to further analysis.

#### 3.2 Differential methylation analysis

While running differential methylation analysis, DMAP produces a list of analyzed regions showing corresponding P-values and the details (such as name of the test, degrees of freedom if applicable) of the statistical test applied. By default, DMAP does not impose any cutoff value to detect DMF or DMR. Users can specify statistics and P-value cutoff to set a threshold for calling DMF or DMR. This provides flexibility to the users and options to apply multiple test corrections methods (e.g. Bonferroni, false discovery rate or Holms methods) and set stringent P-value cutoffs for detecting differential methylation. Table 3 shows an example of candidate fragments after a test has been performed on five human peripheral blood RRBS samples for differential methylation analysis using the $\chi^2$ statistic. A similar analysis can be performed using tiled windows.

#### 3.3 Single CpG investigation

DMAP does not allow detection of differential methylation at single CpG sites; however, if investigation of each CpG is sought, the diffmeth program of DMAP can produce + (methylated) and − (unmethylated) counts for each CpG site within a fragment or tiled window for each sample. Table 4 provides an example of single CpG counts of an MspI fragment in chromosome 1, which contained eight CpG sites for five RRBS samples as produced by diffmeth. Alternatively, single CpG site differential methylation can be performed using methylKit (Akalin et al., 2012a).

</table>

Note: The CpGs column indicates the number of unique CpGs in the fragment. + (methylated) and − (unmethylated) hits gives the total number of counts in the fragment, and the % methylation was calculated from these counts by the diffmeth program in the DMAP package.
3.4 Gene and feature identification

The identgeneloc program of DMAP relates each DMF or DMR (or any regions of interest from reference methylomes) to the nearest gene by comparing the genomic coordinates of the start and the end of the DMF or DMR with the coordinates of the gene and gives relative distances from the transcription start site. identgeneloc considers the sense of the gene (5\' or 3\') and relates the DMF or DMR with respect to the upstream region of the gene. The program includes options for users to impose distance limits on how far valid genes can lie from the fragment. identgeneloc can also provide CpG features (CpG island, shore or core) for a DMF or DMR. Further, for a region internal to a gene, an option is included to return information on whether the fragment is located on an exon, intron or spans over intron/exon or exon/intron boundaries. Table 5 provides an example of an identgeneloc output, showing candidate DMFs, generated from a human RRBS library (annotation source: SeqMonk feature table file). The output is a tab-delimited text file.

3.5 Comparison with other tools

We performed a comparative performance analysis between DMAP, methylKit and BiSeq using test dataset 1, which is available at http://biochem.otago.ac.nz/research/databases-software/.

Note: The identgenloc here provides data of chromosome, length of the region, number of CpG sites contained within the region, P-value, statistical test applied, distance in relation to the gene (calculated from the start of the gene), relationship with the gene (e.g., upstream, exon, intron), CpG feature relation, strand and the name of the associated gene. The — in the gene distance column indicates the region is inside the gene body. The output is a tab-delimited text file, suitable for importing into Microsoft Excel. Gene distance is calculated from the start of the gene.

Test dataset 1 contains two SAM files with uniquely aligned reads for chromosome 1 from a control (2,851,855 reads) and a disease sample (1,122,068 reads). A pairwise test was performed on CpG sites or regions common between both samples. DMAP completed the differential methylation analysis in <3.1 min, which was >5 times faster than methylKit and >10 times faster than BiSeq (Table 6). The main reason for the faster operation of DMAP is that after the alignment—using the SAM files—it is possible to filter fragments (or tiled windows) by coverage, set fold methylation difference criteria and perform a statistical test in one step with a single command. Further, because DMAP is written in C it runs as compiled machine code, and therefore, it executes efficiently. After differential methylation analysis, a second operation of DMAP (performed by identgeneloc) produces gene and CpG feature of the candidate regions. identgeneloc took 1.2 min to complete the second operation for 9,362 investigated fragments in chromosome 1 between the disease and control from test dataset 1.

Analysis by methylKit (version 0.5.7) resulted in 935 DMCs (filtered by CpG coverage of ≥10, DESTRAND = TRUE, q-value of <0.01 and percent methylation difference ≥25%). BiSeq (version 1.2.4) investigated 165,378 clusters and resulted in 402 DMR entries (criteria of min.sites = 20, quantile (totalReads [rbs.clust.unlim]) [ind.cov] > 0.9, minDiff = 0.25, max.dist = 100). Of the BiSeq DMRs, 131 of them were single CpGs. The other 271 regions varied in length; the median length of the DMRs was 18.5 bp and the largest DMR 781 bp. Using the same dataset, DMAP was used to investigate 9,362 common fragments (coverage filter: ≥2 CpGs in a fragment having coverage of ≥10; the F2 110 switch in DMAP) containing 78,318 CpG sites. DMAP identified 367 significant DMFs (basic cutoff = 0.05, adjusted P-value cutoff = 5.34 × 10^-6 after Bonferroni correction). The 367 DMFs contained 3,215 CpG sites (Table 6).

When we compared the co-ordinates of the DMCs derived from methylKit, we found that 318 of 935 DMCs from methylKit overlapped with the CpGs contained within the 367 DMFs identified by DMAP. Similarly, 190 DMCs from methylKit overlapped with CpGs within the 402 DMRs identified by BiSeq. Also, 439 of 1827 CpG sites in BiSeq-identified DMRs overlapped with 3,215 CpG sites in the DMAP-identified DMFs. Overall, 157 CpG sites were identified by all three tools. To investigate if the tools performed better in identifying any particular regions of the genome compared with the others, we mapped the genomic locations of DMCs, DMFs and DMRs identified by methylKit, DMAP and BiSeq respectively (Fig. 2). Using SeqMonk feature table information (based on Ensembl annotation), each region was related to its nearest protein-coding gene and distances from the start of the gene was calculated. DMAP identified higher proportion of promoter-associated regions and lower intronic regions compared to methylKit and BiSeq. However, methylKit identified a higher proportion of CpG sites that were 5 kb or further apart from the transcription start site (TSS > 5 kb) compared to the regions identified by DMAP and BiSeq. All three tools identified similar levels of exonic differential methylation. Further, BiSeq and DMAP identified similar proportion of exonic-intron junction DMRs. Exon-intron junction identification is not possible with methylKit as it identifies DMCs. The CpGs that were common between all the three tools were more prevalent in far upstream of the genes (TSS > 5 kb) and relatively lower in the promoter and introns.

4 DISCUSSION

A higher number of DMCs is expected compared to the number of DMFs/DMRs, because each DMF/DMR will contain several differentially methylated CpGs. DMF/DMR will also contain CpG sites that individually will not qualify as differentially methylated. Further, there will be several independent DMCs that will not form part of a DMF or DMR. This explains the finding of higher DMCs identified by methylKit and lower DMR/DMFs identified by BiSeq and DMAP. A frame-to-frame comparison of differential methylation patterns between these tools is not possible because each of them uses a different unit of analysis to determine differential methylation. The
A fragment-based approach is specific to DMAP whereas methylKit detects DMCs and BiSeq detects DMRs of variable length. Each program uses different statistical tests (see Table 7), different parameters for defining the unit of DNA methylation analysis (i.e., DMR boundaries or DMCs), and different criteria for including CpGs based on coverage. methylKit and DMAP investigate differential methylation in the 4 million CpG sites or 647626 MspI fragments (in a 40–220 bp human RRBS genome), respectively. However, BiSeq considers the spatial arrangement of CpG sites in the genome and defines CpG clusters by specifying a number of frequently covered CpG sites (option: min.sites) that are close to each other (option: max.dist) and uses these clusters for subsequent analysis. Imposing flexible criteria for defining CpG clusters (i.e., lowering min.sites value) in analysis would result in higher number analyzable CpG clusters and higher number of DMRs but might enhance the chances of false discovery. Further, for this analysis we did not specify any DMR cut-off length in BiSeq. Therefore DMCs were also detected in BiSeq as we wanted to include all the possible regions for a fair comparison with methylKit. During the review process, we found that BiSeq version 1.2.0 and 1.2.3 contained an erroneous readBismark function, which produced a very high number of DMRs for our analysis (as a result of false methylation calls), the function was corrected in version 1.2.4. Therefore,

*This analysis was performed on a Mac Pro with 64 bit duo quad core Intel Xeon processors and with 22GB RAM running MacOS 10.7.

aMethylKit produces a CpG.txt file from each SAM file and accepts that as an input to create R object; this step is relatively time-consuming.

*bBiSeq produced a mix of 131 DMCs and 271 DMRs of variable length.

The predictMeth step was relatively time-consuming for BiSeq.

Fig. 2. Overlap and genomic locations of the regions or CpG sites identified by methylKit, DMAP and BiSeq. (A) Overlapping CpG sites between methylKit, DMAP and BiSeq. *For DMAP, 3215 CpG sites are within the 367 DMFs, and 1867 CpG sites are within the 402 DMRs were included. †indicates the overlap between the 3215 sites of DMAP versus 1867 sites of BiSeq. (B) Genomic locations of the 367 DMFs of DMAP. (C) Genomic locations of the 935 DMCs identified by methylKit. (D) Genomic locations of the 402 DMRs identified by BiSeq. (E) Genomic locations of 157 CpG sites that were common to all three programs. Promoters were defined as regions 0–5kb upstream from the start of the gene.
it is advisable to use several tools in combination to ensure detection of sensible detection of differentially methylated regions for biological interpretation.

In terms of coverage, methylKit called the CpG sites with 10 or more reads from the aligned SAM files. In DMAP, fragments having two CpG sites with 10 or more reads were included for analysis. In contrast, BiSeq uses a quantile approach for smoothing methylation data where a higher weighting is given to CpG sites with high coverage and sites with an unusually high coverage are excluded (for example, to the 90% quantile in this analysis). These differences could account for some of the variation observed in the comparative differential methylation analysis performed here.

We present DMAP, an analysis package that filters and processes aligned bisulphite sequenced data to generate comprehensive reference methylomes (tile based and fragment based) with flexibility for users. From SAM files, DMAP provides statistically significant DMRs and relates them to genes and CpGs. Statistical approaches for the analysis of genome-wide methylation data are not yet well characterized. A caveat to the use of statistical tests for fragment or window-based approaches is that methylation values for CpGs within a sequenced read are likely to be correlated, and thus statistical significance can be overestimated. Therefore, further work is needed to devise better statistical methods for accurate detection of differential methylation.

Aside from some awk scripts, DMAP is written in C and executes efficiently. In our test runs, the `diffmeth` program was able to produce a list of candidate regions (while processing 11 human RRBS samples) in 4 h. The output from this step was processed in 20 min by `identgeneloc` to produce gene features of the candidate regions. Although the package was initially developed for the human genome, the code was modified to work with any eukaryotic genome. Optionally, DMAP has no expectation of an X and Y chromosome and can work with any number of autosomal chromosomes. We tested the package with zebrafish genome (Zv9 assembly), which has 25 chromosomes (and no X and Y chromosome), and all the features described in this article worked successfully (Chatterjee et al., 2013). To our knowledge, DMAP is the first tool that accepts unsorted raw SAM alignment files as an input, detects DMR or DMF, provides information and distances of nearest genes and CpG features in relation to each DMF or DMR. The outputs (exported to text files) are relatively easy for bench scientists without bioinformatics expertise to analyze and use with other tools.
